Bioinformatics

West Nile virus (WNV), genus *Flavivirus*, family *Flaviviridae*, is a major cause of viral encephalitis with broad host range and global spread. The virus has undergone a series of evolutionary changes with emergence of various genotypic lineages that are known to differ in type and severity of the diseases caused. Currently, genotyping is carried out using molecular phylogeny of complete coding sequences and genotype is assigned based on proximity to reference genotypes in tree topology. Efficient epidemiological surveillance of WNVs demands development of objective criteria for typing. An alignment-free approach based on return time distribution (RTD) of k -mers has been validated for genotyping of WNVs. The RTDs of complete genome sequences at $k = 7$ were found to be optimum for classification of the known lineages of WNVs as well as for genotyping. It provides time and computationally efficient alternative for genome based annotation of WNV lineages. The development of a WNV Typer server based on RTD is described (<http://bioinfo.net.in/wnv/homepage.html>). Both the method and the server have 100% sensitivity and specificity.

1. Introduction

West Nile virus (WNV; genus *Flavivirus*, family *Flaviviridae*) is a mosquito-borne *Flavivirus* widely distributed across all the continents except Antarctica. It consists of positive sense single stranded RNA genome (~11 kb), enclosed in a ~40–60 nm spherical envelope. The translated polyprotein gives rise to three structural (capsid, pre-membrane and envelope) and seven non-structural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5). The genomic organization and translation mechanism of WNV is similar in principle to other flaviviruses (Brinton, 2001; Westaway et al., 2002; Evans et al., 2011; Pesko and Ebel, 2012). *Passeriformes* birds and culicine mosquitoes are the major hosts in enzootic cycle of WNV and are responsible for the enormity of transmission (Bernard et al., 2001). The large variety of hosts is a key factor in wide dispersal of WNV in the tropical and temperate worlds. Understanding the

relative host specificity exhibited by WNVs is still an open challenge in virology research.

The phylodynamics of WNV lineages has been the area of interest and research for epidemiologist to understand their evolutionary emergence and spread in the last two decades due to the significant health burden posed by it (May et al., 2011; McMullen et al., 2011). Several studies have led to an understanding of the mechanisms of evolutionary emergence and transmission of these viruses across the globe (Anderson et al., 2001; Ebel and Dupuis, 2001; Beasley et al., 2003; Ebel et al., 2004; Davis et al., 2005; Bertolotti et al., 2007; Maes et al., 2009; Armstrong et al., 2011; McMullen et al., 2011).

Based on serological cross-reactivity, WNV is classified into Japanese encephalitic complex of flaviviruses (Calisher, 1989). Based on the molecular phylogeny and analysis of their complete coding sequences, two major lineages (I and II) and two additional lineages (III and IV) of WNV are currently accepted. One putative Spanish lineage of WNV has been recently proposed based on the analysis of NS5 region (Vazquez et al., 2010; McMullen et al., 2011; Pesko and Ebel, 2012). Lineage I is further classified into three clades (a–c) of which clade ‘a’ is further subdivided into 6 clusters. The Indian WNV isolates, which were earlier assigned to putative lineage V (Bondre et al., 2007), have been assigned to the lineage Ic (Lineage I, clade c) in recent publications (May et al., 2011). It may be noted that the terms genotype and lineages are used interchangeably. The members of lineage I are distributed worldwide

and are being studied intensively. The severity and type of disease caused by different lineages of WNVs are dissimilar; for example, NY99 (clade Ia) shows enhanced pathogenesis in birds, whereas the Kunjin virus (clade Ib) exhibits attenuated infection and low neuroinvasion (Brault et al., 2007; Daffis et al., 2011). On the other hand, the severity of the disease caused by the members of lineage II is less and frequency of neuroinvasion is also low. Encephalitis infection caused by lineage II strains in both humans and horses has been reported in South Africa (Venter et al., 2009; Venter and Swanepoel, 2010). Other WNV lineages do not cause mortality but are associated with lower virulence (Davis et al., 2005; Bondre et al., 2007; Hubalek et al., 2010). The differences in processes of migration, adaptation, virulence and neuroinvasiveness in natural hosts and vectors have given rise to worldwide diversity of observed WNV lineages; hence the virus has been termed as an ecological generalist (Pesko and Ebel, 2012). These processes have led to emergence of new lineages, globalization and invasion of WNV (Kilpatrick, 2011). In view of such a wide diversity of WNV, there is need of a web server for rapid identification of the circulating lineages of WNVs for use in diagnosis, control, epidemiological surveillance and further research on the virus.

The present study reports the development of a server for genotyping of WNVs using an alignment-free method developed in-house (Kolekar et al., 2010, 2011, 2012). The method is based on return time distribution (RTD) and has been developed for molecular phylogeny analyses and its applications for genotyping of Mumps viruses and Dengue viruses (Kolekar et al., 2010, 2011, 2012). The current study reports advancement in the RTD-based method to further reduce computations by identifying informative k -mers and thereby enhancing the performance of the method. It also demonstrates applications of the method in large scale whole genome phylogeny, for in silico lineage typing and annotations of WNV genomes.

2. Materials and methods

2.1. Datasets

Following datasets were compiled and curated to benchmark the performance of RTD-based alignment-free method for the genotyping of WNVs. List of entries in the respective datasets with GenBank accession numbers is provided in Appendix A.

2.1.1. Reference dataset

The reference dataset consisted of complete genome sequences (~ 10.3 kb each) of 61 WNVs. The genotype or lineage information for these sequences was available from literature reported earlier (May et al., 2011; McMullen et al., 2011).

2.1.2. True positive dataset

All the available (627) complete genome sequences of WNVs were extracted from *West Nile virus* database available at <http://www.ncbi.nlm.nih.gov/genomes/VirusVariation/Database/select.cgi?taxid=11082> together with their lineage information to the level of clade (as on June 30, 2013). The entries in the reference dataset were excluded. Thus, the true positive dataset consists of 566 entries. The cluster level annotations however were not available for lineage I clade 'a'.

In order to assign the cluster level information to the members of clade 'Ia' in true positive dataset, independent alignment based molecular phylogeny analysis was carried out. The cluster level annotations were assigned based on proximity with the entries of reference dataset. The phylogenetic analysis was carried out using distance based Neighbor-joining method (100 bootstrap replicates) implemented in MEGA 5 package (Saitou and Nei, 1987; Tamura et al., 2011). The multiple sequence alignment (MSA) was obtained using MUSCLE program in the MEGA 5 (Edgar, 2004). The

lineage/clade/cluster information for the entries in this dataset is made available in Appendix A.

2.1.3. Negative dataset

Complete genome sequences of 57 representative members of the family *Flaviviridae* excluding WNV were retrieved from GenBank to compile the negative dataset. True positive and negative datasets were used to evaluate accuracy of the RTD-based genotyping of WNVs using receiver operating characteristic (ROC) analysis.

2.2. Method

Development of an alignment-free RTD-based method and its applications for molecular phylogeny and genotyping of viruses have been reported (Kolekar et al., 2010, 2011, 2012). The method converts the sequence data into return times. Sample sequence and calculation of return time and its parameters is available in the Author's preprint of Kolekar et al. (2012) provided on the server <http://bioinfo.net.in/wnv/homepage.html> under "How RTD works?" pull down. The steps in RTD-based method for molecular phylogeny are (1) compilation of sequence dataset, (2) choice of the value of k , (3) computation of RTDs and their parameters in each sequence at chosen value of k , (4) deriving the pair-wise Euclidian distance matrix and (5) building the phylogenetic tree. The RTD-based genotyping method demands optimization of value of k that leads to genotyping with high sensitivity and specificity (Kolekar et al., 2011, 2012). A brief account of optimization of the value of k for genotyping of WNVs is given below.

2.3. Optimization of value of k for genotyping of WNVs using return time distribution

Initially, the statistical parameters viz., mean (μ) and standard deviation (σ) of each of the 4^k possible RTDs of k -mers in each of the nucleotide sequences of reference dataset were computed separately for varying values of k ranging from 1 to 8 as described earlier (Kolekar et al., 2011). Thus each genomic sequence was represented as the 2×4^k dimensional numeric vector. The Euclidian type pair-wise distance matrix was then derived for each value of chosen k from the respective numeric vectors to infer the Neighbor-joining (NJ) phylogenetic tree (Saitou and Nei, 1987; Kolekar et al., 2012). The value of k for which the WNVs were accurately classified as per the known genotype information was chosen as the optimum value of k for subsequent analysis.

2.4. Selection of informative k -mers at optimized value of k

As the value of k increases, demand on computation and memory also increases. In order to select the informative RTDs of k -mers, the parameters of their RTDs (μ and σ) obtained at optimized value of k (7 in case of WNV) were given as an input to Infogain attribute evaluator with Ranker method assembled in WEKA software (settings as recommended) (Mark et al., 2009). The lineages of WNVs (to the clade level) were used as class labels (Ia, Ib, Ic, II, III, IV). Two sets of informative k -mers, those whose parameters were ranked among the top 100 and the top 200 respectively, were tested independently for their efficacy to resolve the lineages of WNVs.

2.5. Development of server for genotyping of WNVs

The server for genotyping of WNVs, named as "WNV Typer", is developed by using RTD-based alignment-free method with the help of Apache, CGI, PHP architecture and is available in public domain at <http://bioinfo.net.in/wnv/homepage.html>.

3. Results

Since its introduction in New York in 1999, the *West Nile virus* has diversified extensively, which is very evident from the phylogeographic and population genetics studies carried out recently (May et al., 2011; Pesko and Ebel, 2012). In view of these studies, WNVs is expected to continue to evolve into additional genotypic lineages. Therefore, the effective diagnosis and control of WNV epidemics demands methods for genotyping. Classical genotyping approaches requires the identification of complete genome sequences and alignment-based molecular phylogeny analyses (MPA). However, MPA-based genotyping is at times open to subjective interpretation of tree topology. Furthermore, multiple sequence alignment of whole genomes in case of large-scale phylogeny analysis demands high-end computational facility and excessive amount of time. Hence, a new RTD-based alignment-free method for MPA has been developed (Kolekar et al., 2012). Its application for genotyping was demonstrated for mumps and dengue viruses, where empirical cut-off criteria for genotyping were developed using the reference datasets for respective viruses (Kolekar et al., 2011, 2012). The importance of development of pre-computed empirical cut-off for geno/serotyping has resulted in achieving two objectives. The first one is elimination of MSA and MPA while typing new isolates of known geno/serotypes and/or newly emerging novel geno/serotypes. The second objective is development of a user-friendly server to facilitate MPA and typing of viral populations. In case of emergence of new genotype/s, classical MPA requires repeating of the exercise of MSA of all sequences whereas RTD based alignment-free method does not require such compute intensive, time consuming step and only compares the new sequences to pre-computed RTDs of reference dataset. Therefore, to facilitate epidemiological surveillance and to monitor WNV genotypes circulating in the population, an RTD-based server has been developed.

In order to develop the RTD-based genotyping server, a WNV reference dataset was compiled to include representative members of all the four major lineages (I–IV). The lineage I has 3 clades (a–c) where clade 'I-a' is further subdivided into 6 clusters (1–6). These lineages have been determined using extensive molecular phylogeny analysis of complete genome sequences of WNVs. These genome sequences of WNVs are found to differ from each other by 5–25% (Pesko and Ebel, 2012). Recently, an additional putative lineage of WNV from Spain (GenBank: GU047875) has been proposed using molecular phylogeny analysis of NS5 gene (Vazquez et al., 2010). This putative lineage was not included in the reference dataset at present. It could be considered for inclusion in the reference dataset once its lineage status is validated and its complete genome sequence becomes available. Thus, the reference dataset includes all confirmed lineages of WNVs. It was used as a training dataset to optimize value of k for the RTD-based genotyping of WNVs and to validate applicability of the method for WNV genotyping.

The optimization of value of k is the first step in RTD-based genotyping analysis as described and reported earlier in the case of genotyping of *Mumps virus* (Kolekar et al., 2011). In case of WNV, the optimum value of k was found to be 7. It was observed that all the known genotypic lineages and clades of WNV in the reference dataset clustered accurately. Being the only member, Ia6, was found to cluster at the root of Ia5 group. Subsequent availability of multiple strains of Ia6 cluster will help to resolve evolutionary relationships between Ia6 and Ia5 (see Fig. 1).

At $k=7$, the number of RTDs (heptamers) increases to 16,384 (i.e. 4^7). Since each RTD was summarized using two statistical parameters viz. (μ and σ), each complete genome sequence was represented as the numeric vector of size $2 \times 16,384$. The pair wise distances between these numeric vectors in

reference dataset were calculated using Euclidian type distance function described and reported earlier (Kolekar et al., 2011, 2012). The resultant distance matrix was used as an input to NJ method implemented in Neighbor program of PHYLIP package [<http://evolution.genetics.washington.edu/phylip.html>] to infer the phylogenetic tree as shown in Fig. 1. It took ~154 s to infer this phylogenetic tree using RTD-based method, implemented in Perl script on a desktop configuration with 32-bit Windows operating system, 4 GB RAM and 2.80 GHz processor.

It was observed that out of 16,384 possible k -mers (at $k=7$), means of RTDs of ~14,048 k -mers were accounting to zero indicating the absence of "return times" of those k -mers in the complete genome sequence of *West Nile virus* strain EthAn4766 (GenBank: AY603654), as an example. Therefore, there could be many k -mers, which may or may not reappear in all the WNV genomes. Thus, in order to further save the time of analysis while retaining the accuracy of genotyping, it was decided to explore if number of RTDs could be reduced based on their information content. As described in method section, the Infogain feature selection method available in WEKA software was used with recommended settings to score the RTD parameters. Infogain calculates the information gain for parameters of each of the RTDs and rank them based on mutual information content for the purpose of classification. We, thus used k -mers whose RTD based parameters were ranked among top 100 and 200. These two groups of k -mers were independently evaluated using RTD-based approach for their ability to cluster WNVs in known genotypic lineages using the reference dataset. It was observed that the tree topology obtained using the RTDs of top 100 informative k -mers did not corroborate with the known lineage structure of WNVs. However, the parameters of RTDs of k -mers, which were ranked among top 200, were found to be sufficient to accurately resolve all the genotypic lineages of WNVs as shown in Fig. 1. This analysis resulted in significant reduction in the number of computations in RTD-based analysis. Selection of informative RTDs also help in reduction of computational complexity and in saving time that would have been otherwise required for analysis involving all possible 4^k k -mers. It was observed that the time for the analysis decreased from ~154 s to ~3 s without compromising accuracy. Thus, the modification involving use of only informative RTDs in the RTD based phylogeny analyses proved to be successful and resulted in gain with respect to time while maintaining accuracy.

3.1. "WNV Typer" server for genotyping of WNVs using RTD-based method

The successful genotyping of WNVs in reference dataset allowed us to develop the RTD-based genotyping server for WNVs, named here as "WNV Typer". The server accepts the complete genome sequence(s) (~11 kb) of the WNVs in FASTA format through interactive sequence submission form. Upon submission of sequence(s) the CGI script at the backend computes the statistical parameters of RTDs of 200 informative heptamers as reported in the previous section. The Euclidian type distance between query sequences and reference dataset is then calculated. A two-step procedure was adopted to assign the lineage to query sequence. In the first step, the closest reference genotype from reference dataset was identified using the distance measure. In the second step, it was checked whether the distance of the query sequence lies in the precomputed range of distances. In case of failure to meet these criteria, the message "No lineage can be assigned to this query sequence using RTD-based method" will be returned on the 'WNV Typer' server. Thus, the RTD-based method not only helps in substantially reducing time for typing of WNVs but also brings in objectivity in the assignment of lineages. The steps involved in RTD-based genotyping of WNV are shown in Fig. 2. It is to be noted that WNV Typer

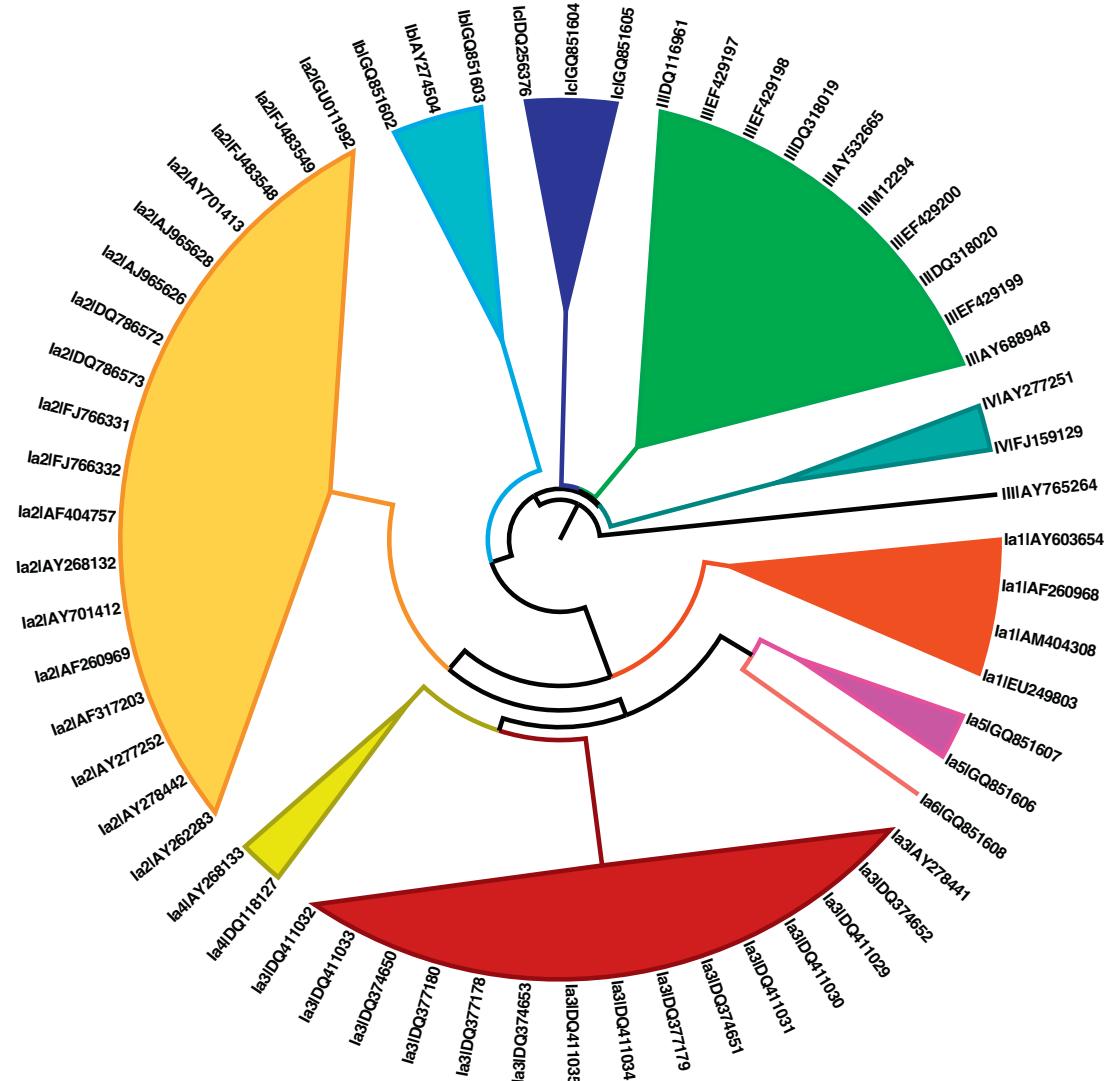

Fig. 1. The phylogenetic tree obtained for the reference dataset of complete genome sequences of *West Nile Virus* using RTD-based alignment-free method at $k=7$. Note: Tip labels in tree are divided into two parts by '!' (pipe) character. First part indicates the genotype of sequence wherein Roman and Arabic numerals respectively indicate lineages and clusters while lower case alphabets indicate the clades as per WNV nomenclature. Second part indicates the GenBank accession number of the sequence. The tree was drawn using FigTree program [<http://tree.bio.ed.ac.uk/software/figtree/>].

predicts the lineage of query sequence up to lineage/clade/cluster level as applicable.

3.2. Validation of performance of the server

In order to assess the performance of WNV Typer, true positive and negative datasets as mentioned in the section of datasets were compiled. The true positive dataset consisted of 566 complete genome sequences of WNVs with known lineage information (only to the clade level) as provided in *West Nile virus* database at National Center for Biotechnology Information (NCBI), Bethesda, USA. The cluster level information was assigned using alignment based molecular phylogenetic analysis. The lineage-clade-cluster data of WNV isolates in reference and true positive datasets are given in [Table 1](#). As listed in [Table 1](#), genomic sequences of lineage Ia4 outnumber other WNV lineages. The RTD based WNV Typer server predicted accurately all the entries in the true positive dataset in accordance with their lineage-clade-cluster level, thus achieving 100% sensitivity. The RTD-based prediction results corroborate with the alignment based molecular phylogeny. However,

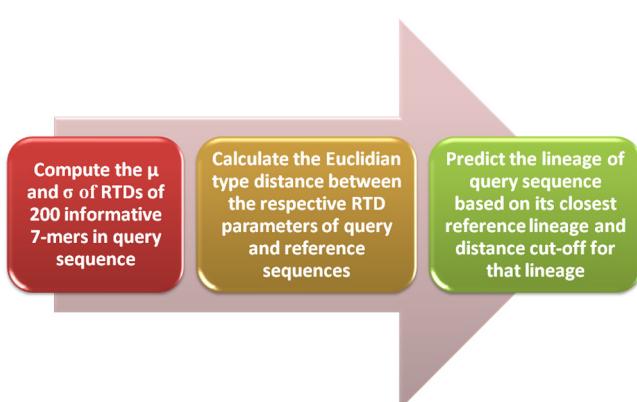

Fig. 2. The steps involved in RTD based method for genotyping of *West Nile viruses* using complete genome sequences.

Table 1

The number of entries in the reference and true positive data sets.

Lineage-clade-cluster	Reference dataset	True positive dataset
Ia1	4	7
Ia2	18	11
Ia3	15	2
Ia4	2	527
Ia5	2	0
Ia6	1	0
Ib	3	6
Ic ^a	3	1
II	10	10
III	1	0
IV	2	2
Total	61	566

^a Putatively known as lineage 5.

it must be mentioned that the true positive sequences for lineage Ia5, Ia6 and III were not available for current round of evaluation.

The negative dataset includes the complete genome sequences of representative members of the family *Flaviviridae*. None of the entries in the negative dataset was assigned to any WNV lineage resulting in 100% specificity of the RTD-based alignment-free WNV Typer server.

4. Discussion

The availability of an increasing number of genome sequences of WNV has facilitated the understanding of WNV evolution in greater detail. In the view of recent epidemics and increasing genomic data of WNVs, it is important to keep track of diverse lineages and their pattern of evolution. In order to achieve this task it is very important to have an efficient mechanism in place to identify and annotate the genomic sequences with lineage/clade/cluster information. Such a mechanism would permit epidemiological surveillance, as well as understanding the phydynamics and pattern of lineage specific disease progression and diagnosis of WNVs. As of now, the lineage specific study of interaction of WNV with Human Leukocyte Antigen (HLA) and Killer immunoglobulin-like receptors (KIR) does not seem to have been done but recently it has been reported that specific KIR genotypes could be connected with WNVs infection (Spiroski et al., 2013). The lineage specific information of WNV would help to investigate whether there is any association between the specific interaction mechanisms adopted by virus and host systems. On the other hand, a strong evidence of correlation has been found between the neuroinvasive virulence phenotype of the WNV infection and the genotype/lineage of the WNV when studied using

mouse model (Beasley et al., 2002). The identification of WNV lineages thus may enable the prediction of the virulence pattern and its consequences, which in turn would assist in diagnosis and treatment of the infection.

The available alignment-based MPA methods, though useful, have a number of limitations. Complexity of analysis is directly proportional to the number and size of genomic sequences. Furthermore, whole analysis starting with MSA needs to be repeated even when a single sequence is to be annotated. In this context, RTD-based alignment-free method proves to be an efficient and accurate option for annotating lineage data of WNV genomic sequences. The development of server using reference dataset adds an advantage by eliminating several steps in conventional MSA based MPA. The molecular phylogeny analysis of 627 complete genomes in reference and true positive datasets using alignment-free RTD approach using 200 informative heptamers required just 10 min for successful completion. Further, the WNV Typer server requires about only 1 s to assign the lineage/clade/cluster per genome sequence providing a distinctive advantage over alignment-based phylogenetic analysis.

5. Conclusions

The return time distribution based alignment-free method was suitably modified and successfully applied for the genotyping of *West Nile viruses*. A web server is made available online and is expected to play a role on lineage/clade/cluster assignment and thus may help in epidemiological surveillance of WNVs. The method provides a robust, scalable and computationally efficient alternative for large-scale genotyping over the conventional MPA analysis.

^a Lineage Ic is putatively known as lineage V.

2. True positive dataset.
